Abstract- Subband Adaptive Filter Architecture techniques have been recently used for subband adaptive filters, since some of the applications such as acoustic echo cancellation and wideband active noise control need adaptive filters with thousands of taps, which result in high computational complexity and low convergence rate. By the use of subband adaptive algorithms, the computational complexity may be reduced along with convergence rate; however, a delay is introduced in the signal path. To remove the delay, the delayless subband adaptive filter architecture open loop structures have been introduced. This paper presents a new open loop delayless subband adaptive filter structure and closed loop suband adaptive filter, where the performance concerning the mean square error of the subband adaptive algorithm, caused due to the aliasing existing in the subband structure, is superior to the results obtained up to now for open loop delayless structures.

In applications like echo sound cancellation and speech enhancement, where there is need to track continuously, adaptive filtering is usually used. Long adaptive filters gives problems like low convergence and high complexity. Subband adaptive filtering has been introduced to overcome these problems. The filter banks used in subband adaptive filtering introduce large delays. In order to compensate for the delays, delayless subband adaptive filtering is introduced. Delayless subband adaptive filtering is used in both open loop and closed loop configuration, where the subband filters are transformed to a fullband filter using a weight.

Keywords - convergence, least mean square, inter symbol interference, nlms, critically subband sampled.

I. INTRODUCTION

Subband adaptive filtering is rapidly becoming one of the most effective techniques for reducing computational complexity and improving the convergence rate of algorithms in adaptive signal processing applications. Discuss the basic principles that underlie the design and implementation of subband adaptive filters. Comprehensive coverage of recent developments, such as multiband tap–weight adaptation, delayless architectures, and filter–bank design methods for reducing band–edge effects are included. Several analysis techniques and complexity evaluation are also introduced in this report to provide better understanding of subband adaptive filtering [1].

Adaptive filtering is a widespread technique in many applications. For acoustic echo cancellation (AEC) hands-free telephony very large adaptive filters are used in system identification on text, whereas in digital communications, adaptive filters perform the channel distortion equalization [2]. The present need for increased throughput in new systems also results in an increase of the equalizer length. In these two
areas, there is a demand for efficient and low complexity algorithms.

II. DELAYLESS SUBBAND ADAPTIVE FILTERING WITH SUBBAND TO FULLBAND TRANSFORM

As subband adaptive filters in general, delayless subband adaptive filters consist of two main parts, a filtering operation and a coefficient adaptation operation. The filtering operation is performed by a fullband filter in the time-domain, see fig. 2. In a practical implementation, a long fullband filter has high computational complexity. In some cases it may be preferable to implement the fullband filter partially in the frequency domain [3].

\[ y(n) = f^T([n/D])x(n) \]  
(1)

where \( f(k) = [f_0(k), \ldots, f_{Lf-1}(k)]^T \) is a vector containing fullband filter coefficients at time instant \( k \). The variable \( k \) denotes the subband signal time index which is related to the full rate time index \( n \) according to \( k = \lfloor n/D \rfloor \) where \( \lfloor . \rfloor \) denotes round-off towards the closest integer towards minus infinity. Vector \( x(n) = [x(n), \ldots, x(n - Lf + 1)]^T \) is the input signal vector. The fullband filter length is denoted by \( Lf \). A fullband error signal \( e(n) \) is obtained as [1]

\[ e(n) = d(n) - y(n) \]  
(2)

Consider a filter bank with \( M \) subbands, causal FIR analysis filters \( h_m(n) \) of length \( L_h \), and decimators with decimation rate \( D \). Input signal \( x(n) \) is decomposed into subband signal \( x_m(k) \) according to

\[ x_m(k) = h_m^T x(kD), \quad m = 0, \ldots, M-1 \]  
(3)

where, \( h_m = [h_{m,0}, \ldots, h_{m,L_h-1}]^T \) and \( x(kD) \) is an input signal vector of corresponding length.

The delayless subband adaptive filter has two operation configurations, open loop and closed loop. In the open loop configuration, the desired signal is decomposed into subband signals as [3]

\[ d_m(k) = h_m^T d(kD) \]  
(4)

and subband error signals \( e_m(k) \) are obtained as

\[ e(n) = d(n) - y(n) = d_m(k) - w_m^T(k)x_m(k) \]  
(5)

where \( w_m(k) = [w_{m,0}(k), \ldots, w_{m,Lw-1}(k)]^T \) is a vector containing the adaptive filter coefficients at time instant \( k \), and \( x_m(k) = [x_m(k), \ldots, x_m(k - Lw + 1)]^T \) is an input subband signal vector. The length of the adaptive filters \( Lw \) is related to the full band filter length \( Lf \) and the decimation rate \( D \) as \( Lw = Lf/D \). In the closed loop configuration, the subband error signals are obtained by decomposing the full band error signal into subband error signals [4].

\[ e_m(k) = h_m^T e(kD) \]  
(6)

In both configurations, a Normalized Least Mean Square (NLMS) algorithm is used in the subbands. Other adaptive algorithms can also be used, such as Recursive Least

\[ w_m(k + 1) = w_m(k) + \mu_m(k)e_m(k)x^*_m(k). \]  
(7)

The time-varying subband step size \( \mu_m \) is calculated
\[ \mu_m(k) = \mu / P_m(k) \]  
\[ P_m(k) = \frac{X_m^H(k)X_m(k)}{L_w} \]  
\[ \mu_m(k) = \mu / P_m(k) \]  
where \( \mu \) is a global step size and \( P_m(k) \) is the short time subband power estimate of the \( m \)th subband signal \( x_m(k) \).

The fullband coefficients are obtained from the subband coefficients by means of a linear coefficient transform

\[ f(k) = Tw(k) \]

where, \( w(k) = [w_0^T(k), \ldots, w_{M-1}^T(k)]^T \) is a adaptive filter coefficient vector at time instant \( k \), and matrix \( T \) is the subband-to-fullband transform.

The open loop configuration is summarized by the equations for all \( n \).

\[ y(n) = f^T([n/D])x(n) \]
\[ x_m(k) = h_m^T x(kD) \]
\[ d_m(k) = h_m^T d(kD) \]
\[ y_m(k) = w_m^T(k)x_m(k) \]
\[ e(n) = d(n) - y(n) \]
\[ P_m(k) = \frac{X_m^H(k)X_m(k)}{L_w} \]

The closed loop configuration is summarized by the equations for all \( n \).

\[ y(n) = f^T([n/D])x(n) \]
\[ e(n) = d(n) - y(n) \]

for all \( k = [n/D] \)
\[ x_m(k) = h_m^T x(kD) \]
\[ e_m(k) = h_m^T e(kD) \]
\[ P_m(k) = \frac{X_m^H(k)X_m(k)}{L_w} \]

\[ \mu_m(k) = \mu / P_m(k) \]  
\[ w_m(k+1) = w_m(k) + \mu_m(k)e_m(k)x_m^*(k). \]  
\[ f(k+1) = Tw(k+1) \]

III. FILTER BANK AND TRANSFORM CONFIGURATION

**Uniform DFT Filter Banks**

A uniform DFT Filter Bank consists of \( M \) analysis filters \( H_m(z) \) (Fig. 3), which are modulated from a prototype filter \( H(z) \) according to[5].

\[ H_m(z) = h(zW_m^m) \]

where \( W_M = e^{-j2\pi/M} \). Let \( A_l(z) = e^{-j2\pi/M} \). Let \( A_l(z) = e^{-j2\pi/M} \).

\[ H(z) = \sum_{l=0}^{M-1} z^{-l} A_l(z) W_m^m. \]

Accordingly, the polyphase decomposition of all analysis filters is given[6]

\[ H_m(z) = \sum_{l=0}^{M-1} z^{-l} A_l(z) W_m^m. \]

\[ f(k+1) = Tw(k+1) \]

**Fig.3 Direct Form Uniform-DFT Filter Bank**

**Analysis Filter Bank Design**

In this section an analysis filter bank design procedure for the delayless subband adaptive filter is described. Lossless power complementary filter banks with minimum phase property is designed. The reason for the use of this design method is that the design procedure is applicable for both uniform-DFT (\( M \)-channel filter bank and tree structured filter banks (two-channel filter bank design). The power complementary constraint for an \( M \)-channel analysis
filter bank is given by \[7\]
\[
\sum_{m=0}^{M-1} |H_m(e^{j\omega})|^2 = 1,
\]

Where, the analysis filters \(H_m(z)\) are derived from a lowpass prototype analysis filter \(H(z)\) with real coefficients according to \(H_m(z) = H(zW_m^M)\). With the spectral factorization \(Q(z) = H(z)H(z^{-1})\), where \(Q(e^{j\omega})\) is a real-valued frequency function and \(Q(e^{j\omega}) \geq 0\) [22], the power complementary constraint can be rewritten
\[
\sum_{m=0}^{M-1} Q(e^{j\omega}W_m^M) = 1.
\]

The transfer function \(Q(z)\) is a zero phase FIR filter with coefficients \(q_i\) [8]
\[Q(z) = \sum_{i=-L+1}^{L-1} q_i z^{-i}.
\]

The power complementary constraint can be transformed to the time-domain according.
\[
\sum_{m=0}^{M-1} q_i W_m^{-mi} = \delta_i,
\]

where \(\delta_i = 1\) for \(i = 0\) and zero otherwise. Since
\[
\sum_{m=0}^{M-1} W_m^{-mi} = \begin{cases} M & \text{for } i = 0, \pm M, \pm 2M, \ldots \\ 0 & \text{otherwise} \end{cases}
\]

IV. SIMULATED AND MEASURED RESULT

Open Loop delayless subband filter result

The identification of a length \(N_p = 512\) FIR system is considered. The input signal is a colored noise sequence generated by passing gaussian white noise by a first-order IIR filter with a pole located at \(z = 0.9\). Experiments open loop delayless filter were performed with the fullband normalized LMS, and with the delayless subband structure of fig. 2 using perfect reconstruction cosine modulated filter banks and \(M = 2\) subbands. The step-sizes were selected such that the best convergence rate \(\mu = 0.1\) presents the MSE evolutions. The new delayless subband structure presents a better convergence rate than the LMS algorithm, due to the power normalization of the step-sizes. It converges to an MSE of the order of the stop band attenuation of the analysis filter (which is around -18 db for \(M = 4\), -16 dB due to the assumption of non overlapping non-adjacent analysis filters Table I [9].

V. CONCLUSIONS & FUTURE WORK

The convergence rate behavior of the open loop and closed loop configurations of the delayless subband adaptive filters architecture is studied. It is shown that the subband-to-fullband transform greatly affects the performance in terms of the fullband mean square error for the open loop configuration and in terms of the convergence speed for the closed loop configuration. It is shown that based on the results for the closed loop case, a transform with optimal convergence performance can be derived. A novel delayless subband adaptive filter is presented, which employs polyphase adaptive filters. This convergence has been analyzed and compared to the behavior of the fullband LMS algorithm through computer MATLAB simulations. We can observe that initially the oversampled subband structure presents better convergence rate. We proposed a closed loop structure with the following features:
1. Less MSE curve.
2. Better convergence.
